

Each systematic over the statistical error, per bin — above the dotted line the systematic dominates
one shared log axis $3\text{e-}09\text{--}1\text{e+}02$; the statistical term is the only one the acceptance changes, so a ϕ cut pushes these ratios down

Drawn as if each run had 4x the counts: δ_{stat} scaled by $1/\sqrt{4}$ and N_{acc} by 4, systematics unchanged.
 δ_{stat} and systabs both carry the same $1/(f_n \cdot 0.6 \cdot 0.86)$ scaling: kinematic-dependent dilution f_n , target polarisation $P_{He} = 0.6$, effective neutron polarisation $P_n = 0.86$.
 $|A_{UT}| \cdot \text{systrel}$ does not — systrel is the quadrature of the relative uncertainties alone (3% target pol, 5% nuclear, 2.5% radiative, 3% diffractive meson, 0.2% random coincidence).
